This version: Nov 2023

Abstract

This paper studies the impact of friction and preferences on match formation in two-sided markets. Because every agent has private information about their preferences for potential matches' characteristics, forming a match based on mutual compatibility requires extensive costly search. We use field experiment data from an online dating platform to better understand the relative impact of search cost and preference on match outcomes. During the field experiment, randomly selected users are provided information about the preferences of their potential partners that can only be obtained through costly search otherwise. We find evidence suggesting that reducing frictions through this information provision leads to less sorting among matched couples in terms of their characteristics. This is because a user often assesses the match probability with a potential partner based on the similarity between their respective characteristics. The information provision allows a user to assess the match probability more accurately using the potential partner's preference rather than characteristics. Consequently, it encourages users to initiate contact with those who are more likely to match despite their characteristics differences, leading to less sorting among matched couples. To investigate the relative contribution of frictions and preferences on assortative matching, we develop and estimate a model that incorporates frictions and preference heterogeneity across users. Our estimation results reveal that frictions play a significant role in shaping matching outcomes. Using model estimates, we simulate matches under the frictionless Gale-Shapley protocol, and we find that removing frictions leads to significantly less sorting between couples. We also find that frictions in our platform lead to a significant reduction in efficiency. These results highlight the importance of platform designs that aim to reduce frictions. More importantly, with one-third of the marriages in the U.S. marriages originating from online encounters, this paper shows how the design of an online platform can contribute to diversity in the marriage market.

1 Introduction

In many two-sided marketplaces, agents search potential partners to form a match based on a mutual agreement.¹ Since agents on both sides of the market have preferences regarding each other’s characteristics, and because these preferences are often private, agents on each side do not know which counterparts are willing to transact.² Forming a match based on mutual compatibility in the presence of private preferences, therefore, generally requires extensive, costly search.

The question of who matches with whom has been a central question in the matching literature. In the presence of costly search, preferences and search frictions both shape the formation of a match. Understanding the relative effects of these two forces on match outcomes is not only theoretically important but also managerially relevant, because the design of online two-sided platforms should vary depending on whether match outcomes primarily result from preferences or search frictions.

In this paper, we try to obtain a better understanding of the relative impact of preferences and various frictions (including search frictions) on match outcomes using data from an online dating platform. We do this in two ways: First, we disentangle the relative impact of preference and frictions on assortative matching (i.e., positive sorting), a widely observed phenomenon where couples display resemblance across various characteristics such as age, education level, ethnicity, and income. Sorting in married couples is an important topic of study—among other things, it exerts long-term effects on economic development and inequality through its impact on the outcomes of children and accumulation of human capital (Raquel and Rogerson (2001); Raquel (2003)). Second, we quantify the gains in user welfare when frictions are removed from the platform. This quantification can offer insights on the gains that users can achieve when better platform designs reduce frictions.

There are two distinct explanations for assortative matching (Hitsch et al. (2010a)): (1) Positive sorting is an equilibrium outcome driven by agents’ preferences. For example, if mate preferences are “horizontal,” people may prefer to match with a similar partner (henceforth, candidates), which in turn results in assortative matching. Or, if mate preferences are “vertical,” in the sense that everyone evaluates candidates using the same criteria, then the ranks of matched partners will be positively correlated. In this case, couples will display positive sorting along attributes that are monotonically

¹Examples can be found across a wide range of industries, including marriage markets, college admissions, online labor markets (TaskRabbit and Upwork), and the hospitality industry (AirBnB).

²Fradkin (2015) shows that more than 40% of booking inquiries on AirBnB platform are rejected. Approximately 14% of those rejections are driven by hosts’ preferences regarding the characteristics of the searcher or the trip.

related with these rankings. (2) Search frictions influence how couples meet, regardless of their preferences. For example, in *offline* dating markets, the existence of couples who attended the same university might not be due to preferences, but instead might reflect the fact that it is more likely for the matched couples to meet and date because they are on the same campus. In reality, *both* preferences and frictions affect how couples meet.

In an *online* dating context, types of search costs vary depending on the platform design. Typically, on online dating platforms (and in the dating market in general) the decision to initiate a date request (or send a message) depends on the probability of the counterpart accepting that request (Bernstein, Stephenson, Snyder, & Wicklund, 1983). As a result, if a user has identical preferences towards two candidates, they should send the date request to the candidate with a higher likelihood of accepting the request. Generally, because people prefer others who are similar to themselves, candidates who are more similar to the focal user are *ex ante* more likely to accept an offer than those who are dissimilar. Therefore, unless a user searches for additional information that helps form a more accurate prediction about the match probability, the user will make the offer to a more similar candidate, which will in turn result in assortative matching. Hence, while assortative matching in online dating platforms may be due in part to people’s preference for others who are similar to themselves, it can also be influenced by search frictions, because users with high search costs will not search for additional information; they will make decisions based only on the limited information provided in the default setting.

The unique feature of our data is that it was generated from a field experiment in an online dating platform. The treatment of the experiment was to provide randomly selected users a piece of information about the preference of their potential matches—an information as to whether a candidate in the profile had *liked* the user. To be specific, many online dating platforms give users the option to *like* a candidate’s profile by either clicking a *like* button or swiping right (similarly, a user can not *like* a candidate by simply not clicking on the *like* button or swiping left). A *like* from the opposite side serves as a positive signal about the likelihood of a successful match; When two users *like* each other, they both get a notification about their mutual *liking*, which can encourage users to start a conversation through messaging. In the default setting (control group), users did not know whether the candidate in the profile had *liked* them. The only way for the focal user to find out was by *liking* the candidate: If the focal user *likes* a candidate, and if the candidate had

also *liked* the focal user, both get notified about the mutual *liking*. If the focal user receives no notification upon *liking* a candidate, this means that the candidate either did not *like* the focal user or has yet to encounter/decide on the focal user’s profile.³

The act of *liking* a profile is costly. While the simple act of clicking a *like* button seems costless, there is a psychological cost associated with the action of *liking*. This cost can be incurred due to several reasons, including: (i) not finding a profile sufficiently appealing, (ii) prospect of not being *liked* back (or not getting a response) by a candidate, which can hurt one’s ego (Baumeister et al. (1993)), or (iii) the possibility of needing to reject a candidate after triggering a positive response from him/her.⁴

Unlike for the control group, who had to incur the above mentioned psychological cost to find out if they were *liked* by the candidate, the experiment allowed the treatment group to know *upfront* whether the candidate had *liked* them, without having to *like* a profile first. Because the majority of initiated messages receive no response, knowing whether someone had *liked* them allows users to more precisely gauge the likelihood of getting a match. Since this information was revealed to the treatment group without them having to take any costly action, the treatment reduced search frictions.

Reciprocity of liking, which is a tendency for people to like others who express liking for them, is well established in nonromantic contexts (e.g., Kenny (1994); Montoya and Insko (2008)). While the validity of these findings in romantic contexts is unclear due to mixed findings (for discussion, see Walster et al. (1973)), research has found that people are reluctant to initiate romantic overtures without some indication that they will be liked in return (Vorauer et al. (2003)). Accordingly, people are less likely to desire a potential partner if the probability of acceptance is low, and are less willing to initiate romantic overtures if the possibility of rejection is salient (Bernstein et al. (1983)). Thus, mate selection decision can be seen as a compromise between a desire for an attractive partner and concerns about rejection. Accordingly, Greitemeyer (2010) show that expectations of reciprocity have a greater impact on people’s desire of the potential partner when the probability of rejection is more salient. Therefore, in our context, we posit that the effect of reciprocity of liking affects users’ “expected” match utility through perceived match probability. In other words,

³The focal user is not able to distinguish between these two causes.

⁴Research in psychology has shown that the object of unwanted affection experiences annoyance and frustration, and that rejecting the romantic overture may cause guilt, discomfort, and other distress (Baumeister et al. (1993)).

knowing that someone has liked them would increase their perceived probability of a successful match, consequently increasing the expected utility derived from such a match.

In the data, we find descriptive evidence suggesting that the treatment changes sorting patterns between matched couples across various dimensions. Specifically, when users matched with those who had *liked* them, couples in the treatment group displayed significant differences in attributes (age, education level, body type, race, popularity) compared to the control group.⁵ Since the treatment reduces search frictions by revealing information about who *liked* them without users having to *like* first to find out, the descriptive patterns we see in the data suggest that reducing frictions can lower the degree of positive sorting between couples.

The mechanism behind this pattern, according to our data, is that the treatment encouraged users to initiate a conversation with candidates who had *liked* them even though they are dissimilar from themselves. In other words, when *liked* by dissimilar candidates, users in the treatment group knew this and were encouraged to initiate a conversation with them. Users in the control group, on the contrary, did not know this information (unless they had engaged in a costly search), and therefore were less likely to initiate a conversation with a dissimilar candidate because they perceived the match probability to be low.

To disentangle the impact of frictions and preferences on assortative matching, and to quantify the impact of frictions on user welfare, we need to compare the matches in a market with frictions to those in a frictionless environment where only preferences shape the matching outcomes. Although the experiment reduced treatment group’s search frictions by providing the information about who *liked* the users without users having to *like* first to find out, some uncertainty nevertheless remains for the treatment group because they may still get no response after sending a message to a candidate despite being *liked* (as will be explained in greater detail below, in this paper we define a “match” as people exchanging several messages back and forth). In addition, if the cost of composing a message is nonnegligible, the decision to start a conversation with a candidate would also depend on the perceived match probability. Therefore, we build a structural model of search for a partner and use model estimates to simulate matches under a counterfactual frictionless environment and compare those to matches formed in the presence of frictions.

⁵We only consider matches where the users of our experiment initiated the conversation through messaging.

More specifically, we model the decision process of a user who is considering whether to search for and to contact a candidate of the opposite gender. Our model incorporates preference heterogeneity across users and also allows for costly search for the information about *likes*. For each candidate’s profile that a user browses, he decides whether to take the costly action of *liking* and/or messaging. This framework allows us to model users’ decisions to search for and contact candidates, and to model how these decisions relate to their preferences and costs. Based on the model estimates, we predict who matches with whom under the default (control) and the frictionless environment. By comparing the matches in the presence of frictions to those in a frictionless environment, we disentangle the relative impact of frictions and preferences on sorting.

We find that frictions play a significant role in shaping assortative matching patterns and that removal of frictions leads to a significant reduction in positive sorting. Specifically, approximately 9% of positive sorting in age, 12% of positive sorting in years of schooling, 40% of positive sorting in popularity, and 21% of positive sorting in race is due to frictions.

We then turn to the question of efficiency by examining how much users gain when all the frictions are removed. To do this, we assign ordinal rankings to each matched partner based on estimated preference parameters and compare the average rankings achieved across different protocols. When all frictions on the platform are removed, the average ranking of the partner leads to a significant improvement of 9.9 percentage points for men and 3.5 percentage points for women in terms of the highest achievable ranking.

The rest of this paper is structured as follows. In Section 2 we review the related literature. Section 3 describes the institutional details of our dating platform. Section 4 details the experimental design. Section 5 summarizes the data, and Section 6 presents descriptive evidence suggesting that reducing frictions may lead to a reduction in positive sorting. In Section 7, we propose a model of search for a partner. Estimation details and estimation results are discussed in Sections 8 and Section 9, respectively. Section 10 presents counterfactual exercises. Section 11 concludes.

2 Related Literature

This paper is closely related to recent literature on frictions in online two-sided markets involving matching. [Fradkin \(2015\)](#) examines search frictions in Airbnb, an online market for short-term rental

housing. [Horton \(2014\)](#) shows that failed transactions due to information frictions are also common in online labor markets, where employers inefficiently pursue oversubscribed workers. While our research and these previous papers all study frictions in two-sided online markets, our focus is on the impact of frictions on assortative matching.⁶

Our paper is also related to empirical work that estimates mate preferences in romantic relationships ([Wong \(2003\)](#); [Choo and Siow \(2006\)](#); [Flinn and Del Boca \(2012\)](#); [Chan et al. \(2015\)](#); [Richards Shubik \(2015\)](#); [Arcidiacono et al. \(2016\)](#)). For example, [Wong \(2003\)](#) uses a two-sided search model to explain marriage outcomes using the Panel Study of Income Dynamics data. [Choo and Siow \(2006\)](#) applies a frictionless transferable utility matching model to the marriage market. While these papers use observed matches in equilibrium to estimate mate preferences, our data document each user’s entire search process. This data enable us to estimate preferences based on users’ actions at each stage of the decision process.

Finally, our paper is also related to the growing literature in speed-dating and online dating ([Kurzban and Weeden \(2005\)](#), [Fisman et al. \(2006\)](#), [Fisman et al. \(2008\)](#), [Lee \(2015\)](#), [Lee and Niederle \(2015\)](#), [Bapna et al. \(2016\)](#)). [Kurzban and Weeden \(2005\)](#), [Fisman et al. \(2006\)](#), and [Fisman et al. \(2008\)](#) use speed-dating data to study mate preferences. [Lee and Niederle \(2015\)](#) study the effect of preference signaling (e.g., sending costly virtual roses with a dating request); they find that the signaling increases the success probability of a dating request. More recently, [Fong \(2018\)](#) studies user behavior in an online dating app, focusing on how users respond to market thickness; [Bojd and Yoganarasimhan \(2019\)](#) study the causal effect of popularity information in online dating; they find evidence of strategic shading due to fear of rejection. [Bapna et al. \(2022\)](#) study how revealing “who likes you” affects user behavior in online dating.

The papers in these areas that are closest to ours are by [Hitsch et al. \(2010a\)](#) and [Banerjee et al. \(2013\)](#). Using data from an online dating website to study the efficiency of matches, [Hitsch et al. \(2010a\)](#) find that the matches predicted by the economic model (Gale-Shapley deferred-acceptance algorithm) are similar to the actual matches achieved on the dating website, suggesting that these matches are approximately efficient. They are also able to largely predict the assortative matching patterns observed in the matches, which suggests that assortative matching can arise

⁶Related research on information frictions and market inefficiency is a paper by [Fr chet te et al. \(2008\)](#). In many scenarios such as markets for new physicians/law graduates, professional athletes drafting, and college admissions, early matches can be inefficient if crucial information for determining the match quality evolves over time.

Note. This figure is for illustrative purpose only.

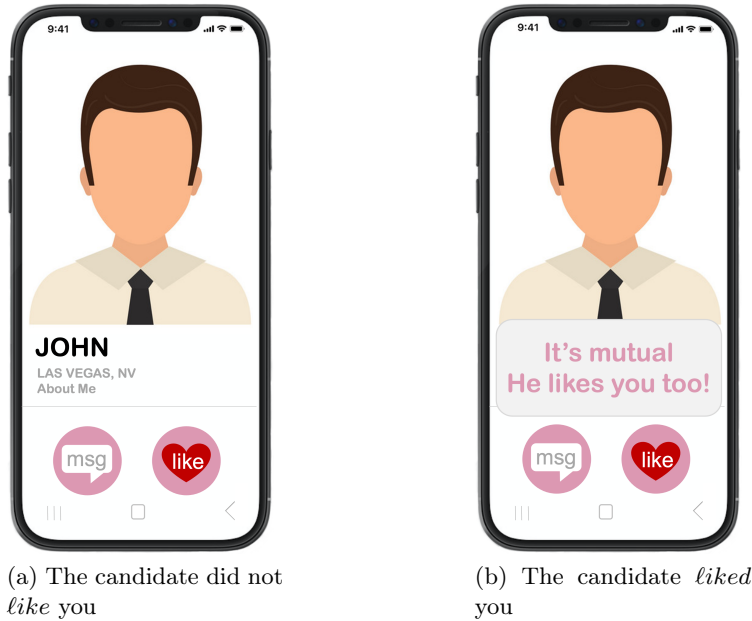

Figure 1: Profile of a Candidate Displayed to the Control Group

in the absence of search frictions, primarily due to preferences and market mechanisms. Using a similar approach, [Banerjee et al. \(2013\)](#) study how preferences for caste can affect equilibrium patterns of matching. They find a very strong preference for within-caste marriages, and they also show that in equilibrium, ignoring caste-related preferences does not alter the matching patterns on non-caste attributes. Compared to these papers, our experiment enables us to detect a source of search friction, which motivates us to disentangle the contribution of friction and preferences on the equilibrium sorting and user welfare.

3 Institutional Details

The online dating platform our data comes from is a typical “freemium” community: most of the users sign up for a free account that allows them to use the basic features (browsing profiles, *liking*, and sending messages) to interact with other members of the platform, while some users pay a monthly subscription fee for a premium account that consists of a fixed bundle of free and premium features, including the ability to know whether the candidate in the displayed profile had *liked* the focal user.⁷

⁷During the period of our study, there was no limit in the number of *likes* and messages that a user could send.

Notes. (For illustrative purposes only. The actual icons and images may be different in the app). This figure illustrates how *liking* a profile reveals whether the candidate had *liked* the focal user or not. The *like* button turns red when the user chooses to *like*. If the candidate had *liked* the focal user, both users receive a notification about the mutual *liking*. In addition to a notification, a heart icon appears in the top right-hand corner. If the candidate had not *liked* the focal user, neither a notification nor a heart icon appears.

Figure 2: How *Liking* a Profile Reveals Information

The platform is accessible through both its website and mobile app. Although the experiment was conducted on randomly selected users who use either type of device, in this paper we focus solely on the users who used the mobile app. In addition, among a few different ways to search for a partner, we only focus on users who were searching for partners through the “rapid matching” process (the actual term of the process is disguised) due to its simplicity.⁸ This process will be described in detail below. Note that our approach is different from ?, who studied user behavior across all search processes, rather than solely focusing on the *rapid matching* process. To begin, we will first describe how the *rapid matching* process works for a mobile app user in the default setting (i.e., a user in the control group with a nonpremium account), then proceed to describe how the experiment changed the operation of the app for users in the treatment group in the following section.

⁸In rapid matching, profiles are displayed sequentially. In non-rapid matching, multiple profiles are displayed simultaneously.

When a nonpremium user in the control group opens the mobile app, a random profile is displayed to him/her.⁹ Figure 1 illustrates what is displayed to a user. A user is able to see the candidate’s profile picture and such characteristics as age, race, and education level. Upon browsing the profile, a user can choose to *like* and/or send a message. A user can choose to *like* by either clicking a *like* button (or by swiping right). Similarly, a user can choose to not *like* by simply not clicking the *like* button (or by swiping left). If the user chooses to *likes* a profile and the candidate had already *liked* the focal user, then both users receive a popup notification about their mutual *liking* (Figure 2b). In addition to the popup notification about the mutual *liking*, a heart icon appears next to the candidate’s profile picture (in the upper right-hand corner) indicating that the candidate had *liked* the focal user.¹⁰ Therefore, *liking* a candidate reveals whether or not the candidate had *liked* the focal user.

If neither a notification nor a heart icon appears upon choosing to *like*, it implies that the candidate had not *liked*, or had not yet seen and *liked*, the focal user (Figure 2a). The focal user is not able to distinguish between these two causes of “not *likes*.”

A user will see a new candidate’s profile immediately after sending a message or clicking the “back” button. Also, if a user swipes in either direction as opposed to clicking the *like* button, a new candidate’s profile will be displayed—unless a mutual *liking* is reached, in which case Figure 2b is displayed and the user can decide whether to send a message. On the other hand, if a user clicks the *like* button instead of swiping right, he can continue browsing the current candidate’s profile (in this case, he/she sees Figure 2a if he/she hadn’t been *liked* and sees Figure 2b if he/she had been *liked*) and has to decide whether to send a message.

4 The Experiment

In this section, we describe the experiment design and how it changed the way the app operated for the treatment group. The experiment was conducted on 100,000 newly registered random users of the platform (either website or the mobile app) over three consecutive months.¹¹ We refer to

⁹The platform shows profiles based on users’ responses to a set of questions, for example, asking how individuals balance their personal needs and those of their partners in a relationship. We assume that the responses to these questions are orthogonal to the observed characteristics of the user.

¹⁰The heart icon is for illustrative purpose only. A different icon may appear in the actual app.

¹¹The target population was randomly selected from among newly registered users during a seven-day period in 2016. These users account for less than 1% of the entire population of the platform’s users as of 2019.

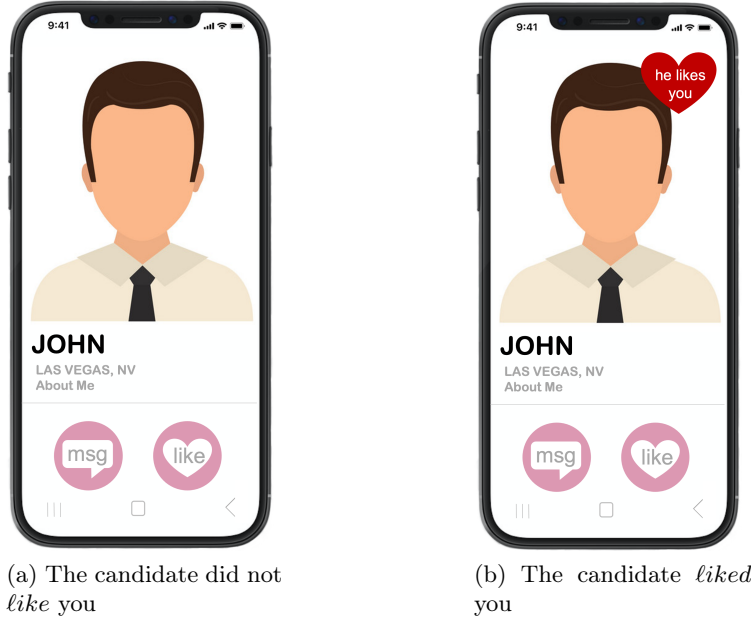

Figure 3: Profile of a Candidate Displayed to the Treatment Group

these months as the pretreatment period (month 1), the treatment period (month 2), and the posttreatment period (month 3).¹² On the first day of the treatment period, 50,000 randomly selected users received the following email:

*Hey username, you have been randomly selected to receive a super power - for the next 30 days, we're giving you the ability to know whether someone had liked you! Normally this feature is restricted to paid premium users only. Enjoy!*¹³

The remaining 50,000 users who serve as our control group received the following email:

Hey username, it's a good time to visit our platform! Enjoy!

Because the treatment was endowed on users by the platform without any required action on the users' part, users were unaware of being part of an experiment; therefore, observer bias wouldn't be present in this study.

Figure 3 illustrates what was displayed to a user in the treatment group when he/she opened the app. When a candidate's profile was displayed to a user, user could immediately see whether he/she was *liked* by the candidate or not. If the user had been *liked* by the candidate, a heart

¹²The gift of treatment expired after 30 days.

¹³To disguise the identity of the platform (and the terminologies specific to it), the messages presented in the paper are slightly modified from the actual messages that were sent to users.

icon appeared in the upper right-hand corner (Figure 3b). If the candidate had not *liked* the focal user, the heart icon was absent (Figure 3a). As mentioned earlier, a user was unable to distinguish whether the candidate had browsed his profile and decided not to *like*, or whether his/her profile was not browsed yet by the candidate..

5 Data Description

For each of the 100,000 users in our experiment, we observe time-stamped actions (browsing, *liking*, and messaging) over the three months. For each user, we have the following self-reported demographic variables: gender, sexual orientation, age, education level, race, and body type.¹⁴ We also observe time-stamped actions and demographics for all correspondent users (i.e., candidates) who had interacted with the experimental users in any way. The data on correspondent users' *liking* behavior allows us to observe who had *liked* the focal user of our experiment. In addition, we observe whether a user was using a desktop or a mobile app, whether a user has a premium account, and whether the account is valid.

Out of the initial sample of 100,000 experimental users, we limit our sample to mobile app users who were searching for a partner using the *rapid matching* process. We further limit our sample to heterosexual users who browsed at least one profile during the treatment period.¹⁵ We drop users with a premium account to avoid selection bias, and we also drop users with a nonvalid account. The final sample consists of 8,142 treated and 7,663 control experimental users. In our data, less than 0.5% of the experimental users interacted with other members of the experiment, and less than 0.5% of the users in the treatment group interacted with other members in the treatment group. Hence, we do not worry about contamination bias.

Table 1 summarizes characteristics of the experimental users in our sample, separately for men and women.¹⁶ We have self-reported information on users' age, education level, body type, and ethnicity. Consistent with existing research that uses data from other online dating services, there are more men than women in our dataset (11,807 men, 3,998 women). Men are on average 31 years old and women are on average 35 years old. Among men and women who reported their education

¹⁴Only a few demographic variables were provided to us, due to privacy concerns.

¹⁵A large number of users became inactive just a few days after creating an account.

¹⁶This table summarizes demographic characteristics of the experimental users only, not correspondent users.

Variable	Men				Women			
	Mean	SD	Median	Obs.	Mean	SD	Median	Obs

White	0.6447	0.4786	1	5,100	0.6101	0.4879	1	2,026
Black	0.0843	0.2779	0	5,100	0.1091	0.3118	0	2,026
Hispanic	0.1082	0.3107	0	5,100	0.1076	0.3100	0	2,026
Other Race	0.0767	0.2661	0	5,100	0.0434	0.2039	0	2,026

Notes. Many users choose not to report some of their demographic information, which leads to different number of observations for each demographic variable. In the data (prior to selecting our sample), we also have users with the following education levels: LawSchool, MedSchool, and PhD. In our final sample, although we do have candidates with these education levels, we do not have experimental users with these education levels. This is because experimental users with these education levels were dropped during our sample selection process (browsed at least one profile, heterosexual, valid, nonpremium, mobile app users).

Table 1: Summary Statistics of Users Characteristics

level, approximately 55% of men and 58% of women received their final degree from a university, and approximately 16% of users have a postgraduate degree. Most users in our dataset are White (64% men and 61% women), followed by Hispanic (11% men and 11% women), Asian (9% men and 13% women) and Black (8% men and 11% women). The test of randomization of the treatment is reported in online appendix.

6 Descriptive Statistics

6.1 Impact of the Treatment on User Activities

We start by showing the effect of the treatment on user activities. From the perspective of the focal user, there are two types of candidates: (1) candidates who had *liked* the focal user (henceforth

Notes. If the difference between the treatment and control group is significant at the 5% level, the t-statistics are in bold.

Table 2: Summary Statistics of User Activities Toward Likers

“Likers”), and (2) candidates who did not *like* the focal user (henceforth “NotLikers”). Since the treatment allows users to know whether the candidate had *liked* him/her or not without having to take any further action, it is natural to think that treated users would behave differently depending on whether a candidate is a Liker or a NotLiker.

In Table 2, we present summary statistics of user activities toward Likers, separately for men and women. Column 1a (2a) summarizes activities of men (women) in the control group, and column 1b (2b) summarizes activities of men (women) in the treatment group. We also report the differences between the control and treatment group (columns 1c and 2c) and t-statistics (columns 1d and 2d) to show whether there are any significant differences between the two groups.

For men, treatment has no significant impact on the total number of profiles that a user browses, but it increases the number of *likes* sent by 13% and increases number of initiated messages sent by 17%. We see a similar pattern for women: treatment has no significant impact on the total number of profiles that a user browses, but it increases the number of *likes* sent by 32% and increases number of initiated messages sent by 34%.

We also test whether treatment has an impact on the number of successful matches achieved by our experimental users. While we do not observe whether users actually went on an offline date or the actual content of the messages exchanged between users, we do observe the number of messages that were exchanged by each pair. Prior research by [Bapna et al. \(2016\)](#) and anecdotal evidence from the online dating industry have pointed out that exchange of three messages between potential couples is a good predictor of an actual online match, in which phone numbers are exchanged or users ask the other out for an offline date. In fact, senior executives of the platform revealed that they strongly believe that this measure of a match is an accurate predictor of an offline date. Moreover, despite knowing the exact content of users’ messages, the platform uses this metric as a measure of a successful match. Following ?, we take a more conservative stance and define a successful match as an exchange of at least four messages. Here we only consider “initiated” matches, where at least four messages were exchanged upon the experimental user starting a conversation. These results are also reported in Table 2. We find that the treatment increases men’s initiated matches with Likers by 12% and increases women’s initiated matches with Likers by 28%. Table 3 presents summary statistics of user activities towards NotLikers. Since treated users are unsure whether the candidate had browsed his/her profile and decided not to *like*, or whether his/her profile was not

browsed yet by the candidate, the effect of treatment on user behavior is ambiguous. Except for the reduction in the number of *likes* sent by men in the treatment group, the treatment does not lead to a significant difference in user activities nor the number of successful matches.

6.2 Frictions and Sorting

Positive correlation in mate attributes has been widely documented and studied in previous research across multiple disciplines. Our experiment reduces the search friction present in our platform for the treatment group by revealing the information about *likes* that users received from candidates without having to take a costly action. Therefore, by looking at how the treatment affects sorting patterns between matched couples, we can get insights into the impact of search frictions on assortative matching.

User attributes in our data are as follows: age, education level (high school = -4, two-year college = -2, university = 0, masters = 2, law school = 3, medical school = 3, PhD = 6), body type (skinny, average heavier, overweight), and race (Asian, Black, Hispanic, White, other). In addition, we create a synthetic variable that measures the popularity of a user, which is the total count of *likes* received divided by the sum of *likes* and “not *likes*” received. Specifically, user i ’s popularity is calculated as:

$$\text{popularity}_i = \frac{\#likesReceived_i}{\#likesReceived_i + \#NotlikesReceived_i}$$

This measure is then standardized to have a mean 0 and standard deviation of 1, separately for men and women.¹⁷

To compare the sorting patterns between the two groups, we first construct a measure of attribute difference (henceforth “attribute difference”) that can be used to test whether treatment leads to a significantly different sorting pattern between a matched man and woman. Specifically, the attribute difference between a man m and a woman w is calculated as $\Delta = |x_m - x_w|$, where x_m and x_w are m ’s and w ’s characteristics, respectively. We obtain the attribute difference between couples for age, education level, popularity, race, and body type. Since race and body type are categorical variables, we construct attribute difference as an indicator variable that takes value 1 when m and w are of different race/body type, and 0 otherwise.

¹⁷We use data of both experimental and correspondent users to calculate the mean and variance when standardizing the popularity measure.

Popularity	0.7493 [2,045]	0.7701	0.8073 [2,563]	0.8051	0.0580	2.4770

Notes. Number of observations in square brackets. For race and body type, we report standard error and z-statistic. If the difference between the treatment and control group is significant at the 5% level, the t-statistics are in bold.

Table 4: Attributes Differences With Initiated Matches

Table 4 displays mean attribute differences and standard deviation (standard error for race and body type) of couples *who matched with Likers*, separately for the control and treatment group. We also report the difference between the two groups (TR-CT) and the t-statistic (z-statistic for race and body type). Interestingly, attribute differences of the treatment group are significantly larger compared to those of the control group, across all dimensions. The age difference between couples in the treatment group ($\Delta = 4.53$) is on average 0.4 years (or 10.2%) greater than the age difference between couples in the control group ($\Delta = 4.11$); The difference in years of education between couples in the treatment group ($\Delta = 1.99$) is on average 0.27 years (or 15.7%) greater than that of couples in the control group ($\Delta = 1.72$); Approximately 61% of the users in the treatment group matched with partners of different race, which is 4 percentage points greater than that of the control group (57 percent); Approximately 62% of the users in the treatment group matched with partners of different body type, which is 5 percentage points greater than that of the control group (57%); The popularity difference between couples in the treatment group ($\Delta = 0.81$) is roughly 8% greater than the popularity difference between couples in the control group ($\Delta = 0.75$).

Tables 5 shows differences in degree of sorting between the treatment and control group when they *matched with NotLikers*. Since the focal user is not able to distinguish whether the NotLiker choose to not *like* the him/her, or whether they have not yet seen the his/her profile, the impact of treatment on assortative matching is ambiguous.

Table 5: Attributes Differences With Initiated Matches

Our results provide evidence suggesting that the treatment reduces the degree of positive sorting between couples. One possible explanation for this is that the treatment encourages users to initiate a match with candidates that seem ex ante unreachable in the absence of treatment. If, generally, attribute difference is negatively correlated with ex ante match probability, users in the default control condition are more likely to initiate a match with a candidate whose attributes are similar to their own. In other words, users in the default control condition are more likely to initiate a match with a similar candidate because similar candidates are more likely to accept the match offer. However, a user who was discouraged from reaching out to a candidate in the control condition due to the (ex ante) low match probability may be encouraged to start a conversation in the treatment condition once he/she sees that the candidate had *liked* him/her. Therefore, in the treatment condition, users may be encouraged to initiate a conversation with Likers whose attributes are different from their own, despite ex-ante low match probability.

To test this, we need to show that treated users are more likely, than control users, to send messages to candidates who are different from themselves, and that these candidates have ex ante low match probability. As a starting point, we first show that users have lower probability of matching (ex ante match probability) with dissimilar candidates compared to similar candidates. To obtain ex ante match probabilities, we use predicted values of a logistic regression where we regress a match indicator (exchanging at least four messages, with each sending at least two messages) on

candidates' characteristics, as well as positive and negative differences between user and candidates' characteristics.¹⁸ Table 6 reports the correlation between attribute difference and ex ante match probability. Except for the body type, attribute difference is negatively correlated with ex ante match probability, suggesting that indeed a match is generally more likely to occur if the pairs are similar in their characteristics.

Having shown that users have ex ante lower match probability with candidates whose attributes are different from their own compared to similar candidates, we now proceed to show that treated users are more likely, than control users, to match with candidates that have ex-ante low match probability. To do so, we need to compare the differences in ex-post match probability between the treatment and control group for different values of ex ante match probabilities. Ex post match probability is calculated as the average value of the match indicator for each percentile of ex ante match probability. To obtain the difference in ex post match probability, we subtract the control group's mean probability of a match with a Liker from that of the treatment group.

Figure 4 (a) plots the distribution of the difference (between the treatment and control group) in ex post match probability with Likers against its ex ante match probability. Specifically, the difference in ex post match probability is obtained by subtracting the control group's mean probability of a match with a Liker from that of the treatment group, separately for each percentile of ex ante match probability. We then plot the mean difference in ex post match probability for each decile of ex ante match probability. The positive value of this difference implies that the treatment group obtained more matches compared to the control group, and vice versa. We find that for sufficiently low values of ex ante match probabilities (e.g., 1st and 2nd decile), differences in match probabilities are positive. Positive (negative) differences for low (high) values of ex ante match probabilities suggest that users in the treatment group are more (less) likely, compared to the control group, to match with Likers of low (high) ex ante match probabilities. We repeat this analysis for matches formed with NotLikers. Results are plotted in Figure 4 (b). Differences in match probabilities are approximately centered around zero, for all values of ex-ante match probabilities.

¹⁸In other words, we regress a binary match variable on right hand-side variables of equation 9 which specifies users' utility from matching with a candidate.

Figure 4: Ex Post Probability of Matching With Respect to Ex Ante Match Probabilities

We have shown that the treatment leads to less sorting when matches are formed with Likers, suggesting that reducing frictions can lead to less sorting between couples. Although the experiment reduced treatment group's search friction by providing the information about who *liked* the users without users having to *like* first to find out, some uncertainty about whether a match will happen nevertheless remains for the treatment group because they may still get no response after sending a message to a candidate despite being *liked*. In addition, if the cost of composing a message is nonnegligible, the decision to start a conversation with a candidate would also depend on the perceived match probability. To disentangle the impact of frictions and preferences on sorting and user welfare, we need to compare the matches formed in a market with frictions to those formed in a frictionless environment where only preferences shape the matching outcomes. Therefore, in the following section, we develop a structural model of costly search and use the model estimates to simulate equilibrium matches in a frictionless environment.

7 The Search Model

We consider an online dating platform where in each period, N_M men and N_W women are searching for a partner. Time is discrete, and we assume that discounting across time is negligible, i.e., the time discount factor $\rho \approx 1$. This assumption is consistent with existing research that uses data from online dating platforms (Hitsch et al. (2010a); Fong (2018)). Each man is indexed by $m \in \mathcal{M} = \{1, 2, \dots, N_M\}$ and has observed characteristics X_m . Similarly, each woman is indexed by $w \in \mathcal{W} = \{1, 2, \dots, N_W\}$ and has observed characteristics X_w . In what follows, we describe the model from the perspective of a male user m . The model is symmetric for a female user w .

In each period, female candidate's profiles are drawn randomly from a distribution F_W and displayed to man m as long as he continues the search for a partner. A match occurs if both m and w agree to go on an offline date, and we assume that the search ends once m gets a match. If at least one does not agree, the search for a partner continues. Following the existing literature, we assume that the distribution of single users' profiles is exogenously given and is stationary over time. To guarantee stationarity, we assume that users who are matched exit the market and are immediately replaced by their "clones," as in McNamara and Collins (1990), Burdett and Coles (1997), Bloch and Ryder (2000), and Adachi (2003).¹⁹

For each candidate w that m browses, he has to pay a cost $c_{M,m}^{browse}$, which can be interpreted as time and cognitive effort spent on viewing the profile. Then, for each w 's profile, m first needs to choose action $d_{mw} \in \{\text{like}, \text{nlike}\}$, which indexes his decision to *like* or not *like* w 's profile ($d_{mw} = \text{like}$ if *like*, and $d_{mw} = \text{nlike}$ if not *like*). Then, he needs to choose action $\mu_{mw} \in \{\text{msg}, \text{nmsg}\}$, which indexes his decision whether or not to send a message to w ($\mu_{mw} = \text{msg}$ if message, and $\mu_{mw} = \text{nmsg}$ if not message). Let us denote these two decision stages as the *liking stage* (LS) and the *messaging stage* (MS), respectively.

There are two types of users, treated ($\tau_m = 1$) and control ($\tau_m = 0$).²⁰ At the liking stage, in contrast to treated users who know the true value of ℓ_{wm} which equals 1 if w had *liked* m and 0 otherwise (as previously mentioned, the reason for "not *like*" is not distinguishable to m), users in the control group do not observe the true value of ℓ_{wm} unless they choose $d_{mw} = \text{like}$ at the

¹⁹A clone of a man m has identical characteristics as man m .

²⁰We distinguish control and treated users in our model is because calculating reservation values under the frictionless environment for the counterfactual requires us to obtain reservation values of both types of users.

liking stage. Therefore, control users form an expectation about ℓ_{wm} conditional on their own and w 's characteristics. The information structure of m depends on his type τ_m , the stage he is in $s \in \{LS, MS\}$, and his action $d_{mw} \in \{\text{like}, \text{nlike}\}$ at the liking stage.

Denote $\mathcal{L}_{wm}^{s, \tau_m}$ as the expected value of ℓ_{wm} that user of type τ_m has about ℓ_{wm} at stage $s \in \{LS, MS\}$. $\mathcal{L}_{wm}^{LS, \tau_m}$ is summarized as

$$\mathcal{L}_{wm}^{LS, \tau_m} = \begin{cases} \ell_{wm} & \text{if } \tau_m = 1 \\ \mathbb{E}[\ell_{wm}|X_m, X_w] & \text{if } \tau_m = 0. \end{cases} \quad (1)$$

The exact value of ℓ_{wm} will be revealed to control users if they choose $d_{mw} = \text{like}$ at the liking stage. Therefore, at the messaging stage, all users *except* those in the control group who have chosen to not *like* a profile will observe the true value of ℓ_{wm} . $\mathcal{L}_{wm}^{MS, \tau_m}$ can then be summarized as

$$\mathcal{L}_{wm}^{MS, \tau_m} = \begin{cases} \ell_{wm} & \text{if } \tau_m = 1 \\ \ell_{wm} & \text{if } \tau_m = 0 \quad \& \quad d_{mw} = \text{like} \\ \mathbb{E}[\ell_{wm}|X_m, X_w] & \text{otherwise.} \end{cases} \quad (2)$$

Denote Ω_{mw}^{s, τ_m} as the information that m of type τ_m has about w at stage $s \in \{LS, MS\}$. The information set of m about w at the liking stage is given as $\Omega_{mw}^{LS, \tau_m} = \{X_w, e_{mw}, \mathcal{L}_{wm}^{LS, \tau_m}\}$ and the information set at the messaging stage is given as $\Omega_{mw}^{MS, \tau_m} = \{X_w, \mathcal{L}_{wm}^{MS, \tau_m}, e_{mw}\}$. In what follows, we first describe the details of the *messaging stage*, then we describe the details of the *liking stage* in a backwards induction manner.

7.1 Messaging Stage

Let $V_M(m)$ denote m 's expected utility of remaining single and continuing the search for a partner. For the moment, let us suppose that $V_M(m)$ is given. Man m receives a utility of $u_{M, mw}$ by matching with a woman w . Denote $V_{M, mw}^{MS}(\mu_{mw}|d_{mw}, \Omega_{mw}^{MS, \tau_m})$ as m 's expected utility from choosing action μ_{mw} conditional on his choice $d_{mw} \in \{\text{like}, \text{nlike}\}$ at the liking stage and his information set Ω_{mw}^{MS, τ_m} .

Then we have

$$V_{M,mw}^{MS}(\mu_{mw}|d_{mw}, \Omega_{mw}^{MS, \tau_m}) = \begin{cases} -c_{M,mw}^{\text{msg}} + u_{M,mw} \cdot \mathbb{E}_m [P_{W,mw}(d_{mw}, \mu_{mw}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})] \\ \quad + V_M(m) \cdot \left(1 - \mathbb{E}_m [P_{M,mw}(d_{mw}, \mu_{mw}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})]\right) & \text{if } \mu_{mw} = \text{msg} \\ u_{M,mw} \cdot \mathbb{E}_m [P_{W,mw}(d_{mw}, \mu_{mw}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})] \\ \quad + V_M(m) \cdot \left(1 - \mathbb{E}_m [P_{M,mw}(d_{mw}, \mu_{mw}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})]\right) & \text{otherwise} \end{cases} \quad (3)$$

If m decides to send a message, he has to pay a cost $c_{M,mw}^{\text{msg}}$, which can be interpreted as (1) time and effort to compose a message, or (2) aversion to experiencing negative emotions in case w does not respond or agree to go on a date (match). $P_{M,mw}(d_{mw}, \mu_{mw}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})$ is the probability that w will match with m upon m initiating a match, and is a function of d_{mw} and μ_{mw} conditional on X_m, X_w, ℓ_{wm} , and Ω_{mw}^{MS, τ_m} . When m does not know the true value of ℓ_{wm} , he forms an expectation about the match probability conditional on the information Ω_{mw}^{MS, τ_m} that he knows about w .

If m sends a message, he incurs a cost $c_{M,mw}^{\text{msg}}$ and gets utility $u_{M,mw}$ with expected probability $\mathbb{E}_m [P_{M,mw}(d_{mw}, \text{msg}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})]$, but with probability $1 - \mathbb{E}_m [P_{M,mw}(d_{mw}, \text{msg}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})]$ he does not get a match and remains single and continues the search. On the other hand, even if m does not send a message, he may nevertheless get a match with positive expected probability $\mathbb{E}_m [P_{M,mw}(d_{mw}, \text{nmsg}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})]$ if $d_{mw} = \text{like}$. This is because, if both m and w like each other, the information that m liked w is revealed to w , which affects w 's decision to initiate a message to m . We assume that if m neither *likes* nor messages w , the match probability is zero, i.e., $\mathbb{E}_m [P_{M,mw}(\text{nlike}, \text{nmsg}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})] = 0$.²¹ Moreover, since sending a message is a stronger signal of interest than simply *liking*, we assume that as long as m sends a message to w , his decision at the liking stage becomes irrelevant, i.e., $\mathbb{E}_m [P_{M,mw}(\text{like}, \text{msg}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})] = \mathbb{E}_m [P_{M,mw}(\text{nlike}, \text{msg}|X_m, X_w, \ell_{wm}, \Omega_{mw}^{MS, \tau_m})]$. Then, m will choose to message w if and only if

$$V_{M,mw}^{MS}(\mu_{mw} = \text{msg}|d_{mw}, \Omega_{mw}^{MS, \tau_m}) \geq V_{M,mw}^{MS}(\mu_{mw} = \text{nmsg}|d_{mw}, \Omega_{mw}^{MS, \tau_m}) \quad (4)$$

²¹Note that this is an initiated match probability, which is the probability of matching upon m initiating a match either through a *like* or a message.

7.2 Liking Stage

At the liking stage, if m chooses $d_{mw} = \text{like}$, he receives utility $c_{M,mw}^{\text{like}} + \varepsilon_{mw}^{\text{like}}$, where $c_{M,mw}^{\text{like}}$ is the psychological cost of *liking* and $\varepsilon_{mw}^{\text{like}}$ is an error term observed by m (but unobserved by the researcher) that affects m 's decision to *like* w .²² Similarly, if m does not *like* w , he receives $\varepsilon_{mw}^{\text{nlike}}$. Error terms $\varepsilon_{mw}^{\text{like}}$ and $\varepsilon_{mw}^{\text{nlike}}$ are distributed i.i.d Type I EV, denoted as $G(\varepsilon)$. We assume that if $c_{M,mw}^{\text{like}} = 0$, both error terms $\varepsilon_{mw}^{\text{like}}$ and $\varepsilon_{mw}^{\text{nlike}}$ equal zero and that m always chooses $d_{mw} = \text{like}$. This assumption will be useful later, when we show the connection between the outcomes of our model and those of the Gale-Shapley centralized model, because when $c_{M,mw}^{\text{msg}} = 0$, one can see with a bit of algebra that the condition in equation 4 reduces to $u_{M,mw} \geq V_M(m)$, in which case m 's decision to *like* does not affect the current-stage utility nor his decision at the messaging stage.

The choice-specific expected utility at the liking stage from choosing d_{mw} when the information available about w is Ω_{mw}^{LS, τ_m} can be written as

$$V_{M,mw}^{LS}(d_{mw}|\Omega_{mw}^{LS, \tau_m}) = \begin{cases} -c_{M,mw}^{\text{like}} + \varepsilon_{mw}^{\text{like}} + E_m \{ \max_{\mu_{mw}} [V_{M,mw}^{MS}(\mu_{mw}|d_{mw} = \text{like}, \Omega_{mw}^{LS, \tau_m})] \} & \text{if } d_{mw} = \text{like} \\ \varepsilon_{mw}^{\text{nlike}} + E_m \{ \max_{\mu_{mw}} [V_{M,mw}^{MS}(\mu_{mw}|d_{mw} = \text{nlike}, \Omega_{mw}^{LS, \tau_m})] \} & \text{if } d_{mw} = \text{nlike}. \end{cases} \quad (5)$$

m will choose $d_{mw} = \text{like}$ if and only if

$$V_{M,mw}^{LS}(d_{mw}=\text{like}|\Omega_{mw}^{LS, \tau_m}) \geq V_{M,mw}^{LS}(d_{mw}=\text{nlike}|\Omega_{mw}^{LS, \tau_m}) \quad (6)$$

Let $V_{M,mw}^{LS}(d_{mw}|\Omega_{mw}^{LS, \tau_m}) = \bar{V}_{M,mw}^{LS}(d_{mw}|\Omega_{mw}^{LS, \tau_m}) + e_{mw}^{d_{mw}}$. Since $\varepsilon_{mw}^{\text{like}}$ and $\varepsilon_{mw}^{\text{nlike}}$ follow i.i.d Type I EV distribution, the probability of choosing $d_{mw} = \text{like}$ is

$$\Pr(d_{mw} = \text{like}) = \frac{\exp(\bar{V}_{M,mw}^{LS}(\text{like}) - \bar{V}_{M,mw}^{LS}(\text{nlike}))}{1 + \exp(\bar{V}_{M,mw}^{LS}(\text{like}) - \bar{V}_{M,mw}^{LS}(\text{nlike}))} \quad (7)$$

²²As explained earlier, the psychological cost of *liking* can be incurred due to several reasons, such as (i) not finding w sufficiently attractive, (ii) prospect of being rejected by w , or (iii) the possibility of having to reject w 's overtures after triggering her response by *liking* her.

7.3 Latent Utility

We assume that preferences for potential partners depend on observed own and candidate's attributes, and idiosyncratic preference shock e_{mw} , which follows i.i.d logistic distribution:

$$u_{M,mw} = u_M(X_m, X_w; \Theta_M) + e_{mw} \quad (8)$$

where $X_M = (x_m, x_m^d)$ and $X_W = (x_w, x_w^d)$ are m 's and w 's observed characteristics which follow a distribution F_M and F_W , respectively. x_m and x_w are vectors that have continuous values, and x_m^d and x_w^d are sets of categorical variables. Θ_M is a vector of parameters that represent m 's preferences.

The latent utility that m gets if he matches with w is parameterized as

$$\begin{aligned} u_M(X_m, X_w; \Theta_M) = & x_w' \beta_M + (|x_w - x_m|'_+) \beta_M^+ + (|x_w - x_m|'_-) \beta_M^- \\ & + \sum_{r,s=1}^N \mathbb{1}\{x_{mr}^d = 1 \text{ and } x_{ws}^d = 1\} \cdot \beta_{M,rs}^d \end{aligned} \quad (9)$$

where $|x_w - x_m|_+ = \max(x_w - x_m, 0)$ and $|x_w - x_m|_- = \max(x_m - x_w, 0)$.²³ Dummy variables x_{mr}^d and x_{ws}^d indicate whether m and w have certain categorical characteristics. The set of preference parameters to be estimated is $\Theta_M = (\beta_M, \beta_M^+, \beta_M^-, \beta_M^d)$ and $\Theta_W = (\beta_W, \beta_W^+, \beta_W^-, \beta_W^d)$.

7.4 Negligible Costs and Equivalence With Gale-Shapley Stable Matches

In this subsection, we provide a link between the outcomes of a decentralized search model and stable matches of the Gale-Shapley marriage model. The Gale-Shapley marriage problem assumes the presence of a central matchmaker which recommends a matching to agents given individuals' preferences over potential partners, and hence does not describe the online matching process wherein agents have to incur costs to find a partner in the absence of a central matchmaker. [Adachi \(2003\)](#) shows, however, that as search costs become negligible, the set of equilibrium matches obtained in a two-sided search and matching model is identical to the set of stable equilibrium matches predicted by the Gale-Shapley algorithm. Moreover, repeated rounds of offer-making and corresponding rejections of the deferred-acceptance algorithm resemble the search and messaging behavior of the users on online dating platforms ([Hitsch et al. \(2010a\)](#)). Since the stable matching predicted by the

²³In other words, $|x_w - x_m|_+$ is the difference between m and w 's attributes if this difference is positive, and $|x_w - x_m|_-$ is the absolute value of this difference if this difference is negative.

Gale-Shapley algorithm is also Pareto-optimal, it also provides a theoretical efficiency benchmark that can be used to quantify the loss of efficiency caused by frictions in our platform.

Consider a hypothetical condition where all costs are removed, i.e. $c_{M,mw}^{\text{like}} = c_{M,mw}^{\text{msg}} = 0$, and consider m 's decision problem of whether to send a message to w . If $c_{M,mw}^{\text{msg}} = 0$, the condition in equation 4 reduces to

$$u_{M,mw} \geq V_M(m). \quad (10)$$

The match probability no longer appears in equation 10, and m sends a message as long as the utility from a match is greater than the expected value of continuing the search. Since m 's decision at the *liking* stage does not affect his decision at the messaging stage, m 's decision to *like* will only depend on the error terms $\varepsilon_{mw}^{\text{like}}$ and $\varepsilon_{mw}^{\text{nlike}}$. To make a connection between the outcomes of our model to those of the Gale-Shapley centralized model, we will make a simplifying assumption that when $c_{M,mw}^{\text{like}} = c_{M,mw}^{\text{msg}} = 0$, both error terms $\varepsilon_{mw}^{\text{like}}$ and $\varepsilon_{mw}^{\text{nlike}}$ equal zero. Then since the decision to *like* does not affect the utility, we will assume that m always chooses $d_{mw} = \text{nlike}$. In this case, m 's expected utility of staying single and continuing the search can be defined by the following Bellman's equation:

$$\begin{aligned} V_M(m) &= V_{M,mw}^{LS}(d_{mw} = \text{like} | \Omega_{mw}^{LS, \tau_m}) \\ &= \rho \int u_{M,mw} \cdot A_M(m, w) A_W(m, w) + V_M(m) (1 - A_M(m, w) A_W(m, w)) dF_W(w) \end{aligned} \quad (11)$$

where

$$A_W(m, w) = \mathbb{I}\{u_{W,mw} \geq V_W(w)\} \quad \text{and} \quad A_M(m, w) = \mathbb{I}\{u_{M,mw} \geq V_M(m)\} \quad (12)$$

Similarly, woman w 's expected utility of staying single can be written as

$$V_W(w) = \rho \int u_{W,w} \cdot A_W(m, w) A_M(m, w) + V_W(w) (1 - A_W(m, w) A_M(m, w)) dF_M(m) \quad (13)$$

The system of equations 11 and 13 define a monotone iterative mapping that converges to a profile of reservation utilities $(V_M^{GS}(m), V_W^{GS}(w))$ solving the system, and hence characterize the stationary equilibrium in this market.

Adachi (2003) shows that as $\rho \rightarrow 1$, the set of equilibrium outcomes in a decentralized search model reduces to the set of stable matchings in a corresponding Gale-Shapley marriage problem. A

stable match is defined, following [Gale and Shapley \(1962\)](#), as a pairing where there are no pairs (m, w) who are willing to abandon their partners and match with each other. Specifically, [Adachi \(2003\)](#) shows that the system of Bellman equations 11 and 13 coincide with the following system of equations characterizing the set of stable matchings in a Gale-Shapley marriage problem:

$$\begin{aligned} V_M^{GS}(m) &= \max_{\mathcal{W} \cup \{m\}} \{u_{M,mw} | u_{W,wm} \geq V_W^{GS}(w)\} \\ V_W^{GS}(w) &= \max_{\mathcal{M} \cup \{w\}} \{u_{W,wm} | u_{M,mw} \geq V_M^{GS}(m)\} \end{aligned} \quad (14)$$

where $V_M^{GS}(m)$ and $V_W^{GS}(w)$ is the expected utility of staying single in a frictionless environment for man m and woman w , respectively. If time is not discounted, and if there are no costs (costs of browsing, as well as the costs of *liking* and messaging) each man (woman) continues the search process until he (she) finds a woman (man) such that $u_{M,mw} \geq V_M^{GS}(m)$ ($u_{W,wm} \geq V_W^{GS}(w)$). Then a man will be matched with the best woman who is willing to match with him, and vice versa, which is how the set of stable matchings are characterized in Gale-Shapley problem.

8 Estimation

8.1 Match Probability

We obtain users' expectations about the match probability for each stage separately from the model. There are two match probabilities in our model, (i) $P_{W,mw}(d_{mw} = \textit{like}, \mu_{mw} = \textit{nmsg} | X_m, X_w, \ell_{wm})$ which is a match probability from sending only a *like*, and (ii) $P_{W,mw}(d_{mw}, \mu_{mw} = \textit{msg} | X_m, X_w, \ell_{wm})$ which is a match probability from sending a message.²⁴

To obtain $\mathbb{E}_m [P_{W,mw}(d_{mw} = \textit{like}, \mu_{mw} = \textit{nmsg} | X_m, X_w, \ell_{wm}) | \Omega_{mw}^{LS, \tau_m}]$, we use the predicted values from estimating the following linear probability model:

$$Match_{wm}^{\textit{like}} = u_W(X_m, X_w; \Theta_W) + \psi^{\textit{like}} \mathcal{L}_{wm}^{LS, \tau_m} + \xi_m + e_{1,wm} \quad (15)$$

²⁴Recall that we assumed $\mathbb{E}_m [P_{M,mw}(\textit{like}, \textit{msg} | X_m, X_w, \ell_{wm}) | \Omega_{mw}^{MS, \tau_m}] = \mathbb{E}_m [P_{M,mw}(\textit{nlike}, \textit{msg} | X_m, X_w, \ell_{wm}) | \Omega_{mw}^{MS, \tau_m}]$

$Match_{wm}^{\text{like}}$ as a binary variable that equals 1 if m and w match (exchange at least 4 messages) when m likes w but does not send a message to w , and 0 otherwise.²⁵ Here $u_W(\cdot)$ is defined similarly as in equation 9. The parameter ψ^{like} measures the impact of w 's like on the match probability.

The endogeneity of $\mathcal{L}_{wm}^{LS, \tau_m}$ is a potential concern. It is possible that unobserved high compatibility between m and w leads to a higher likelihood of w liking m , leading to a biased estimate of ψ^{like} . Some users might be inherently more compatible with others, resulting in higher number of likes. We address this endogeneity problem by including user fixed effects, ξ_m .

Similarly, to obtain $\mathbb{E}_m[P_{W,mw}(d_{mw}, \mu_{mw} = \text{msg}|X_m, X_w, \ell_{wm})|\Omega_{mw}^{MS, \tau_m}]$, let $Match_{wm}^{\text{msg}}$ be a binary variable that equals 1 if m and w match after m sends a message to w , and 0 otherwise. We estimate the following linear probability model and use predicted values from this regression as $\mathbb{E}_m[P_{W,mw}(d_{mw}, \mu_{mw} = \text{msg}|X_m, X_w, \ell_{wm})|\Omega_{mw}^{MS, \tau_m}]$:

$$Match_{wm}^{\text{msg}} = u_W(X_m, X_w; \Theta_W) + \psi^{\text{msg}} \mathcal{L}_{wm}^{MS, \tau_m} + \eta_m + e_{2,wm} \quad (16)$$

where η_m is user fixed effect. Parameter ψ^{msg} measures how much w is more likely to match with m in response to his message if she has liked him. As before, we control for unobserved user compatibility using fixed effects.

8.2 Reservation Value

In this subsection we describe how we estimate $V_M(m)$ and $V_W(w)$ in the presence of frictions. We will describe how to obtain reservation values in the absence of frictions, i.e., $V_M^{GS}(m)$ and $V_W^{GS}(w)$, in Section 10.1.

We assume that $V_M(m)$ and $V_W(w)$ remain constant across different profiles. Ideally, we want to estimate these reservation values using user-specific fixed effects, following [Hitsch et al. \(2010a\)](#) and [Banerjee et al. \(2013\)](#). But not only is this approach computationally burdensome due to the large number of users in our sample, it is also unsuitable in our setting due to the selection issue: to include user-specific fixed effects, we need to drop users who haven't liked or messaged any profiles. However, dropping these individuals may lead to biased estimates because higher costs of liking and messaging may prevent certain users from liking and messaging. Therefore, we group

²⁵Note that here we index the subscript as wm as opposed to mw . This is to reflect w 's preferences and decision to accept m 's offer

users with similar observed characteristics and estimate their reservation values using group fixed effects instead of individual user fixed effects, as users with similar characteristics are likely to have similar reservation values. Using this approach allows us to keep all users in the data even if they haven't *liked* or messaged any profiles. Specifically, we use K-means clustering to partition users into groups. *K*-means is an unsupervised learning approach that partitions the dataset into *K* predefined nonoverlapping clusters. Each user is assigned to a cluster such that the sum of the squared distance between the users' characteristics and the cluster's centroid (arithmetic mean of all users' characteristics that belong to that cluster) is at the minimum. We classify users into five clusters based on their observed characteristics X_m , separately for each type τ_m (total 10 clusters).

8.3 Likelihood

We maximize the joint likelihood of m 's decision at the liking and messaging stages for each profile that he browses. The likelihood of our model is given as

$$L = \prod_{m=1}^{N_M} \prod_{w=1}^{J_m} \left(\Pr_{d,mw} \cdot \Pr_{\mu,mw|d,mw}^{\delta_{mw}} (1 - \Pr_{\mu,mw|d,mw})^{1-\delta_{mw}} \right)^{\vartheta_{mw}} \times \left((1 - \Pr_{d,mw}) \cdot \Pr_{\mu,mw|d,mw}^{\delta_{mw}} (1 - \Pr_{\mu,mw|d,mw})^{1-\delta_{mw}} \right)^{1-\vartheta_{mw}} \quad (17)$$

where $\Pr_{d,mw}$ is the probability that m *likes* w , $\Pr_{\mu,mw}$ is the probability that m messages w , and J_m is the total number of profiles that m browses. ϑ_{mw} indicates the decision made at the liking stage ($\vartheta_{mw} = 1$ if $d_{mw} = \text{like}$, $\vartheta_{mw} = 0$ otherwise), and δ_{mw} indicates the decision chosen at the message stage ($\delta_{mw} = 1$ if $\mu_{mw} = \text{msg}$, $\delta_{mw} = 0$ otherwise).

8.4 Identification

Identification is difficult in models where costs and preferences are interdependent. This is because *liking* w could be due to high preferences for w 's characteristics, or it could be due to the low cost of *liking*. Similarly, messaging w could be due to high preference for w 's characteristics or could be due to the low cost of messaging. Correspondingly, we rely on an exclusion restriction to separately identify preferences from costs. When there is at least one covariate that enters the cost function but not the utility function, that covariate can serve as an exclusion restriction for identification.

We specify the cost of *liking*, $c_{M,mw}^{\text{like}}$, as

$$c_{M,mw}^{\text{like}} = \exp(\lambda_0 + \lambda_1 \mathcal{L}_{wm}^{LS, \tau_m} + \lambda_2 \text{age}_m + \lambda_3 \text{popularity}_m) \quad (18)$$

where $\mathcal{L}_{wm}^{LS, \tau_m}$ is a function of ℓ_{wm} at the liking stage, as described in equation 1.²⁶ One would expect ℓ_{wm} (whether w liked m) to have an effect on m 's cost of *liking*, as w *liking* m will lower m 's psychological burden of *liking* w . For more details on the psychological cost of *liking*, see Section 1. In our model, ℓ_{wm} (or its expectation) enters the expected utility net of costs ($c_{M,mw}^{\text{like}}$ and $c_{M,mw}^{\text{msg}}$) only through its impact on match probability. Since the predicted match probability is estimated separately from the model as described in Subsection 8.1, ℓ_{wm} does not enter the expected utility function and hence can serve as an exclusion restriction and help to separate the cost from the utility.

We also include m 's characteristics as variables that influence the cost of *liking*. Among various characteristics, we believe age and popularity level to shift the cost of *liking*. Age can influence the psychological burden of *liking* someone due to more or lack of experience in the dating market. We also expect popularity level to affect the cost of *liking*, either through boost in confidence, or through experiencing greater negative emotion when *liking* an unappealing profile. Unlike age and popularity, race, education level and body type are less likely to have an influence in one's participation in the dating market. Therefore, we do not include these variables into the cost function.

Similarly, the expected cost of messaging is parametrized as

$$c_{M,mw}^{\text{msg}} = \exp(\gamma_0 + \gamma_1 \mathcal{L}_{wm}^{MS, \tau_m} + \gamma_2 \text{age}_m + \gamma_3 \text{popularity}_m) \quad (19)$$

where $\mathcal{L}_{wm}^{MS, \tau_m}$ is a function of ℓ_{wm} as at the messaging stage (see equation 1).

²⁶ As described earlier, the information set of a user depends on the type of the user, his actions, and the stage that he is in.

Table 7: Preference Parameter Estimates

9 Estimation Results

Table 7 reports the maximum likelihood estimates of preference parameters, separately for men and women. Our estimation results are, generally, consistent with the findings of prior research (Kurzban and Weeden (2005); Fisman et al. (2006); Hitsch et al. (2010a); Hitsch et al. (2010b)). Both genders prefer partners who are young, and while men tend to have greater preference for

Table 8: Cost Parameter Estimates

women whose age is similar to their own, women prefer men who are older than them. With regards to education level, men’s preferences are opposite of women’s. Men prefer women with less years of education, while women prefer men with more years of education. Nevertheless, both genders tend to prefer candidates whose education level is greater than their own. We find that both genders prefer candidates with average body types to those who are heavy and overweight. Men show a strong preference for women with an average body type, while women show a strong distaste for men who are overweight. Moreover, men prefer being bigger than their female partners. We also find that popularity is an important determinant of preference for both genders. Both men and women prefer more popular candidates, but women tend to place greater emphasis on popularity than men. While men prefer women whose popularity is similar to their own, women prefer partners who are more popular than themselves. Finally, both men and women generally have a relative distaste for a candidate of a different race, but most of the coefficients on women’s race preference are not statistically significant.

Table 8 Panel A reports parameter estimates of costs of *liking*. Cost of *liking* is significant and has important implications for user’s search behavior. As expected, for both men and women, the coefficient on $\mathcal{L}_{wm}^{LS, \tau_m}$ is negative. This suggests that users are more likely to *like* a candidate who is also more likely to *like* (or has *liked*) them. Age and popularity, on the other hand, has opposite effect for men and women. Older age and greater popularity increases the cost of *liking* for men, but reduces the cost of *liking* for women. Table 8 Panel B reports parameter estimates of costs of messaging. The coefficient on $\mathcal{L}_{wm}^{s, \tau_m}$, similarly to the cost of *liking*, is negative for both

genders. For both genders, the cost of messaging is significant, and the constant term is greater than that of the cost of *liking*. For both men and women, greater age and popularity lowers the cost of messaging.

10 Predicted Matching Patterns

We quantify the impact of frictions and preferences on assortative matching and user welfare. Specifically, we compare the equilibrium matches achieved (1) in a default setting where everyone is in the control group, and (2) equilibrium matches in a frictionless environment. This comparison allows us to quantify the relative impact of frictions and preferences on sorting, and also the impact of frictions on user welfare.

For matches achieved in the default setting, instead of using the actual matches that are observed in the data, we will simulate the matches using our structural model (see section 10.1). The costs of liking and messaging prevent users from reaching out to many candidates, which in turn leads to different sets of candidates ending up with a match across different protocols. To make a correct comparison across protocols, the initial pool of available candidates in the market must be identical across different protocols. Therefore, we use all and only the users who are part of the experiment (11,807 men and 3,998 women) as our initial pool of men and women attempting to find a partner, and simulate matches among these users.

We simulate equilibrium matches in a frictionless environment using the Gale-Shapley deferred-acceptance algorithm. Predicted matches under the default control setting are obtained by introducing frictions to the deferred-acceptance algorithm using the structural model. This is similar to [Banerjee et al. \(2013\)](#) where they introduce ad-hoc constraints to the deferred-acceptance algorithm to account for search frictions.

In what follows, we describe how we compute predicted matches in a frictionless environment using the Gale-Shapley deferred-acceptance algorithm. The process of computing equilibrium matches when users engage in costly *liking* and messaging can be found in the online appendix.

10.1 Empirical Strategy

The man-optimal stable matching using the deferred-acceptance algorithm is executed as follows:

1. All men first propose to their most highly ranked woman, as long as $\hat{u}_{M,mw} \geq V_M^{GS}(m)$.
2. Among all the offers that each woman receives, she selects the most highly ranked man, as long as $\hat{u}_{W,wm} \geq V_W^{GS}(w)$.
3. All men who haven't been selected then propose to their second most highly ranked woman.
4. If a woman receives a new offer that is higher-ranked than the one she is currently holding, the woman releases the old offer and keeps the new offer. Released man then has to propose to the next woman in his ranking list.
5. This process continues until all men go through all women such that $\hat{u}_{M,mw} \geq V_M^{GS}(m)$.

Ties are broken randomly. The above process describes how we obtain a set of stable matches implied by the estimated preferences when frictions are negligible.

To compute the stable matches using the Gale-Shapley deferred-acceptance algorithm, we need to obtain reservation values in the absence of frictions, i.e., $V_M^{GS}(m)$ and $V_W^{GS}(w)$. We use the following procedures to obtain $V_M^{GS}(m)$ for each user m :

1. For each m , we calculate m 's utility for each candidate that he browses using estimated preference parameters, then we calculate the average utility over all candidates, i.e., $E_w[u_{M,mw}]$
2. Next, we regress $V_M(m)$ on $E_w[u_{M,mw}]$, $E_w[c_{M,mw}^{like}]$, $E_w[c_{M,mw}^{msg}]$ and their respective squared terms
3. Then we obtain the fitted value of $\hat{V}_M(m)$ while setting $E_w[c_{M,mw}^{like}]$ and $E_w[c_{M,mw}^{msg}]$ to zeros.
4. We use this fitted value of $\hat{V}_M(m)$ as $V_M^{GS}(m)$.

Note that the cost of browsing, $c_{M,m}^{\text{browse}}$, is omitted from the regression. This is because we do not estimate $c_{M,m}^{\text{browse}}$ separately in our model, but instead only estimate $V_M(m)$, which can be written as $V_M(m) = -c_{M,m}^{\text{browse}} + \max \left\{ V_{M,mw}^{LS}(d_{mw} = \text{like} | \Omega_{mw}^{LS, \tau_m}), V_{M,mw}^{LS}(d_{mw} = \text{nlike} | \Omega_{mw}^{LS, \tau_m}) \right\}$. While $c_{M,mw}^{like}$ and $c_{M,mw}^{msg}$ may be correlated with $u_{M,mw}$ through user characteristics' association with ℓ_{wm} , there

is no reason to believe that $c_{M,m}^{\text{browse}}$ is correlated with $u_{M,mw}$, because we assume that the cost of browsing is constant across candidate profiles. However, it is highly likely that $c_{M,m}^{\text{browse}}$ is positively correlated with $c_{M,m}^{\text{like}}$ and $c_{M,m}^{\text{msg}}$, which can in turn lead to biased estimates of effects of $c_{M,m}^{\text{like}}$ and $c_{M,m}^{\text{msg}}$. Since we are interested only in fitted values of $\hat{V}_M(m)$ and not regression coefficients per se, any bias in coefficients of $c_{M,m}^{\text{like}}$ and $c_{M,m}^{\text{msg}}$ will absorb the effect of $c_{M,m}^{\text{browse}}$. Therefore, we are not too concerned about the omission of $c_{M,m}^{\text{browse}}$.

Next, we need to construct ordinal preferences (i.e., rankings) over the entire set of women (men) for each man (woman) using estimated preference parameters from the model. Specifically, estimated preference parameters from the model are used to construct the utility that each man would get from matching with each woman in the market (and vice versa for women) using the following equation:

$$\hat{u}_{M,mw} = u_M(X_m, X_w; \hat{\Theta}_M) \quad (20)$$

Predicted utility $\hat{u}_{M,mw}$ is then transformed into an ordinal ranking $R_m(w)$ of user m with respect to woman w as

$$R_m(w) = n \quad \text{if} \quad \begin{cases} \hat{u}_{M,mw'} > \hat{u}_{M,mw} > \hat{u}_{M,mw''} \\ \text{and } R_m(w') = n - 1 \text{ and } R_m(w'') = n + 1 \end{cases} \quad (21)$$

where n is an integer. We apply this methodology to all users in the sample to obtain a full set of ordinal preferences for each user with respect to all users of the opposite gender.

10.2 Frictions and Assortative Matching

Table 9 reports the mean attribute difference between couples for predicted matches under the assumption of control (CT) and frictionless (GS) environments. We also report the 95 percent confidence intervals of the difference. When we completely remove frictions, we observe a significant increase in attribute difference between couples, compared to the control setting (except for body type in male-optimal matches). For example, when we look at male-optimal matches, the age difference between couples is 5.03 years in the control setting and 5.63 years in the frictionless setting. This suggests that approximately 11% of the positive sorting in age is due to frictions and

	Control (CT)		Gale-Shapley (GS)		GS – CT
	Mean	SD	Mean	SD	95% CI
Men-Optimal					
Age	5.0363 [1,895]	3.3434	5.6365 [2,115]	4.9920	[0.3340, 0.8664]

Education	1.4653 [293]	1.0733	1.9422 [408]	1.5652	[0.2692, 0.6846]
Popularity	0.6091 [2,030]	0.3812	0.7041 [2,528]	0.5381	[0.0673, 0.1227]
BodyType	0.5306 [464]	0.4401	0.6094 [580]	0.4565	[0.0239, 0.1337]
Race	0.4602 [526]	0.4592	0.5728 [657]	0.4699	[0.0592, 0.1660]

Notes. This table reports the mean attribute difference for matches achieved with Likers across 100 simulations. Average number of matches across simulations is in square brackets.

Table 9: Attribute Correlations in Predicted Matches

89% is due to preferences.²⁷ The difference in years of education between couples is 2.10 years in the control setting and 2.36 years in the frictionless setting. Similarly, approximately 11% of the positive sorting in years of education is due to friction and 89% is due to preferences. For popularity, 9% of the positive sorting in popularity is due to friction and 91% is due to preferences. Finally, 11% of the positive sorting in race is due to friction and 89% is due to preferences.

We find similar patterns in female-optimal matches. The age difference between couples is 5.3 years in the control setting and 6.34 years in the frictionless setting, attributing approximately 16% of sorting in age to frictions. The difference in years of schooling between couples is 1.47 years in the control setting and 1.94 years in the frictionless setting, attributing 24% of the sorting in years of schooling to frictions. For popularity, 13% of the positive sorting in popularity is due to frictions, and 19% of the positive sorting in race is due to frictions.

Table 10: Changes in Welfare

10.3 Welfare Analysis

In this section, we quantify the departure from efficiency caused by frictions on the platform by comparing matches formed in control and frictionless settings. Following [Hitsch et al. \(2010b\)](#), we implement this as follows: For each user, we assign an ordinal ranking to all candidates based on the predicted utility. If there are N candidates, the most desirable candidate will be ranked N^{th} , the second desirable candidate will be ranked $N - 1^{\text{th}}$, and so forth. For each user $i \in \{m, w\}$, let R_i^{CT} be the rank of i 's matched partner predicted under the control setting, and R_i^{GS} be the rank of i 's matched partner predicted under the frictionless setting. Denote $\Delta R_i^{GS-CT} = R_i^{GS} - R_i^{CT}$ as the difference between the ranks achieved under the different scenarios, where CT and GS are indexes denoting control and frictionless protocols, respectively. Denote $\Delta \bar{R}^{GS-CT}$ as the mean difference in ranks across users. Then, if $\Delta \bar{R}^{GS-CT}$ is positive, GS setting could have improved, on average, on the allocation from setting CT .

In Table 10 Panels A and B, we report means, medians and standard deviations of predicted average rank differences across protocols for men-optimal and women-optimal equilibrium, respectively. In men-optimal matches, when we completely remove all frictions, men experience an improvement in their partner's rankings by 132.6 and women experience an improvement in partner ranking by 245.4 compared to the control setting. To interpret the magnitude of this difference, we can express the rank differences as a percent of the highest achievable rank ($100 \times \Delta \bar{R} / N$), which gives us rank improvement of 3.4 percentage points for men and 2.1 percentage points for women. We find similar patterns in women-optimal matches. The average difference between the Gale-Shapley matches and the control matches is 387.1 for men and 418.9 for women (improvement of 9.9 percentage points for men and 3.5 percentage points for women).

11 Conclusion

This paper investigates the impact of frictions on the formation of a match in two-sided markets. With agents on both sides having private preferences regarding each others’ characteristics which are often private, finding a match based on mutual agreement requires extensive costly search. Using data from an online dating platform, we estimate a model of costly search for information that incorporates preference heterogeneity across users. Our estimation results reveal that frictions play a significant role in shaping matching outcomes. Our counterfactuals reveal that couples matched in a frictionless environment display greater difference in attributes (in terms of age, education level, race, and popularity), compared to couples who matched in a market with frictions. We also find that removing frictions lead to significant gains in terms of partner rankings.

Our findings provide important managerial implications for the pricing of premium features, in how much users are willing to pay for an additional piece of information about the preferences of the other side. In addition, our findings shed light on what type of information should be displayed on users’ profiles. Information that is helpful in gauging the preferences of other users can greatly improve consumer experience. Our findings are not limited to online dating contexts; they are broadly applicable to other two-sided market contexts where matches may not form due to imperfect information about each other’s preferences.

Our paper also provides insights into how the design of online platforms can contribute to diversity, given that one-third of U.S. marriages now originate from online encounters. However, due to data limitations, we are unable to quantify the long-term effects of reducing frictions, such as the impact on marriages and the accumulation of human capital through children’s education. Future research should aim to address this gap, as quantifying the long-term effects of reducing frictions in online dating platforms can provide solutions to alleviating persistent social inequality.

C Matching Algorithm with Frictions

In this section, we describe how we incorporate frictions to the Gale-Shapley algorithm in the default control setting. Since we are only using the pool of experimental users (who were either assigned to the treatment or control group) to form the two sides of the market, we need to simulate the values of ℓ_{wm} . That is, we simulate the *likes* that a user receives from the opposite gender before he engages in search, for each pair of m and w . Specifically, the simulation of ℓ_{wm} and matching in an environment with frictions is executed as follows:

1. Construct the *likes* that women send to men for each pair of users (w, m) as follows:
 - (a) Draw random utility terms, e_{wm} , for each pair of w and m .²⁸
 - (b) For each w , using the draw and estimated preference parameters, construct the expected utility from *liking* and not *liking* given her information set, i.e.,
$$E_w \left\{ \max_{\mu_{wm}} \left[V_{W,wm}^{MS}(\mu_{wm} | d_{wm} = \textit{like}, \Omega_{wm}) \right] \right\} \text{ and } E_w \left\{ \max_{\mu_{wm}} \left[V_{W,wm}^{MS}(\mu_{wm} | d_{wm} = \textit{nlike}, \Omega_{wm}) \right] \right\}$$
 - (c) w decides to *like* m if the expected utility from *liking* is greater than its cost:

$$\ell_{wm} = \begin{cases} 1 & \text{if } E_w \left\{ \max_{\mu_{wm}} \left[V_{W,wm}^{MS}(\mu_{wm} | d_{wm} = \textit{like}, \Omega_{wm}) \right] \right\} \\ & - E_w \left\{ \max_{\mu_{wm}} \left[V_{W,wm}^{MS}(\mu_{wm} | d_{wm} = \textit{nlike}, \Omega_{wm}) \right] \right\} + \varepsilon_{wm}^{\textit{like}} - \varepsilon_{wm}^{\textit{nlike}} > c_{W,w}^{\textit{like}} \\ 0 & \text{otherwise} \end{cases} \quad (22)$$

2. Taking ℓ_{wm} constructed in the previous step as given, create ordinal preferences of the “expected” utility for each user, for all users of the opposite gender
 - (a) Draw the random utility term, e_{mw} , for each pair of m and w .
 - (b) For each pair m and w , m first chooses $d_{mw} \in \{\textit{like}, \textit{nlike}\}$. m chooses $d_{mw} = \textit{like}$ if and only if

$$E_w \left\{ \max_{\mu_{wm}} \left[V_{W,wm}^{MS}(\mu_{wm} | d_{wm} = \textit{like}, \Omega_{wm}) \right] \right\} - E_w \left\{ \max_{\mu_{wm}} \left[V_{W,wm}^{MS}(\mu_{wm} | d_{wm} = \textit{nlike}, \Omega_{wm}) \right] \right\} + \varepsilon_{mw}^{\textit{like}} - \varepsilon_{mw}^{\textit{nlike}} > c_{M,m}^{\textit{like}} \quad (23)$$

²⁸As opposed to Banerjee et al. (2013), who assume that the noise in the utility function comes from a measurement error, we follow Hitsch et al. (2010a), who assume that the error term is a “structural noise.” This is because several important dimensions of the profile (such as picture or income) that affect choice and are observed by users are unobserved by the econometrician, whereas researchers in Banerjee et al. (2013) observe everything that is observed by the agent.

- (c) Conditional on d_{mw} , m then chooses $\mu_{mw} \in \{\text{msg}, \text{nmsg}\}$. m chooses $\mu_{mw} = \text{msg}$ iff

$$V_{M,mw}^{MS}(\mu_{mw} = \text{msg}|d_{mw}, \Omega_{mw}) \geq V_{M,mw}^{MS}(\mu_{mw} = \text{nmsg}|d_{mw}, \Omega_{mw}) \quad (24)$$

- (d) For each m , compute the predicted expected utility $E\hat{U}_{mw}$:

$$\begin{aligned} E\hat{U}_{mw} &= u_{M,mw} \cdot \mathbb{E}_m [P_{W,mw}(d_{mw}, \mu_{mw}|X_m, X_w, \ell_{mw}, \Omega_w)] \\ &\quad + V_M(m) \cdot \left(1 - \mathbb{E}_m [P_{M,mw}(d_{mw}, \mu_{mw}|X_m, X_w, \ell_{mw}, \Omega_w)]\right) - c_m^{\text{like}} \mathbb{1}\{d_{mw} = \text{like}\} - c_m^{\text{msg}} \mathbb{1}\{\mu_{mw} = \text{msg}\} \end{aligned} \quad (25)$$

- (e) Transform $E\hat{U}_{mw}$ into ordinal ranking $R_m(w)$ such that

$$R_m(w) = n \quad \text{if} \quad \begin{cases} E\hat{U}_{M,mw'} > E\hat{U}_{M,mw} > E\hat{U}_{M,mw''} \\ \text{and } R_m(w') = n - 1 \text{ and } R_m(w'') = n + 1 \end{cases} \quad (26)$$

where n is an integer.

3. Compute equilibrium matches:

- (a) Define I_m as the set of all profiles that m either *liked* or messaged.
- (b) All men first propose (either message or *like*) to their most highly-ranked woman within the set I_m . Ties are broken randomly.
- (c) Women consider all offers they receive. If a woman received a message from a man, the net utility of selecting this man becomes $u_{W,w} - V_W(w)$. On the other hand, if a woman only receives a *like* from a man but did not receive a message, the net utility from selecting this man becomes $u_{W,w} - c_{W,w}^{\text{msg}} - V_W(w)$. This is because if a woman only receives a *like*, she must initiate a conversation with a man, which is costly. Woman selects a man that gives the highest net utility as long as it is greater than zero.
- (d) All men who haven't been chosen by women then propose to the next best woman within the set I_m .
- (e) If a woman receives a new offer that is preferable to the one she is currently holding, she releases the previous offer. The released man then has to propose to the next woman on his list within the set I_m .

- (f) Steps 3 (a) through (e) continue until each man m exhausts the list of women in his set I_m .
